(Received 6 August 2008; published 2 October 2008)

We report detailed measurements of the low temperature magnetic phase diagram of \( \text{Er}_2\text{Ti}_2\text{O}_7 \). Heat capacity and time-of-flight neutron scattering studies of single crystals reveal unconventional low-energy states. \( \text{Er}^{3+} \) magnetic ions reside on a pyrochlore lattice in \( \text{Er}_2\text{Ti}_2\text{O}_7 \), where local \( \text{XY} \) anisotropy and antiferromagnetic interactions give rise to a unique frustrated system. In zero field, the ground state exhibits coexisting short and long-range order, accompanied by soft collective spin excitations previously believed to be absent. The application of finite magnetic fields tunes the ground state continuously through a landscape of noncollinear phases, divided by a zero temperature phase transition at \( \mu_0H_c \sim 1.5 \) T. The characteristic energy scale for spin fluctuations is seen to vanish at the critical point, as expected for a second order quantum phase transition driven by quantum fluctuations.

Despite intense study spanning more than a decade, highly frustrated magnetism in the rare-earth-metal titanate pyrochlores defies a thorough understanding [1]. The pyrochlore lattice is a network of corner-sharing tetrahedra, and the archetype for geometrical frustration in three dimensions [2]. The rare-earth titanates, in particular, have a tendency towards novel physics, due to a conspiracy of energy scales where dipolar interactions and crystal field anisotropy are of comparable importance to the exchange energy between magnetic moments. Exotic behaviors attributed to these pyrochlores include spin ice [3] and spin liquid [4] ground states, magnetoelastic fluctuations near zero temperature [5], emergent magnetic monopole excitations [6], and order-by-disorder [7,8].

Previous studies of \( \text{Er}_2\text{Ti}_2\text{O}_7 \) identify an antiferromagnetic insulator, with a Curie-Weiss temperature of \( \theta_{\text{CW}} \sim -22 \) K [7,9]. Crystal field analysis yields \( \text{XY} \) anisotropy such that the magnetic moments of the \( \text{Er}^{3+} \) ions, with effective magnitude \( \sim 3\mu_B \) [7], are confined to planes tangential to the local tetrahedra on which they reside. Heat capacity [9] and neutron diffraction [7,10] measurements show a continuous phase transition to long-range order at \( T_c \sim 1.1 \) K in zero field. Using the group theoretical language of previous work [7,10], the observed magnetic order is a sixfold degenerate ground state labeled under the basis vector \( \varphi_2 \) of the irreducible representation \( \Gamma_5 \). This ground state is predicted for a simple nearest neighbor exchange model with planar anisotropy [7], where it has been shown to be selected by thermal fluctuations in an example of what Villain described as order-by-disorder [11]. However, it is surprising that this simple model should accurately describe \( \text{Er}_2\text{Ti}_2\text{O}_7 \), where dipolar interactions are expected to be an important perturbation and should select a different ground state [12]. Therefore, the possibility that this ground state is selected energetically by a more complicated microscopic Hamiltonian, rather than via order by disorder, has not been ruled out.

Single crystals of \( \text{Er}_2\text{Ti}_2\text{O}_7 \) were grown using the floating zone technique and a two-mirror image furnace, in 3 atm. of air and at a growth rate of 5 mm h\(^{-1}\). Heat capacities were measured for a 3 mg crystal using the relaxation calorimetry method with a \( ^3\text{He} \) insert. A similar 7.3 g single crystal was selected for the neutron measurements, which were performed using the NG4 Disk Chopper Spectrometer [13] at the National Institute of Standards and Technology Center for Neutron Research.

Heat capacity measurements of single crystal \( \text{Er}_2\text{Ti}_2\text{O}_7 \) (Fig. 1) in zero applied magnetic field recreate the previously reported anomaly at \( T_c \sim 1.1 \) K, which signals the second order phase transition to long-range magnetic order. Under the application of modest magnetic fields along the crystallographic [110] direction, the anomaly remains sharp, but shifts to lower temperature, finally disappearing at a critical field value \( \mu_0H_c \) slightly larger than 1.5 T. For fields of 1.75 T and above a broad feature resembling a Schottky anomaly is seen, at a temperature that depends linearly on the applied field strength. This is suggestive of a crossover to a quantum paramagnetic high-field state, reminiscent of that of the prototype transverse field quantum critical magnet \( \text{LiHoF}_4 \) [14–16].
Knowing the location of the phase boundaries, we now focus on the nature of the different phases. To this end, high quality single crystals of Er$_2$Ti$_2$O$_7$ were studied by the time-of-flight neutron scattering technique. This allows a simultaneous measurement of both the elastic and inelastic neutron scattering cross-section within the $\frac{1}{2}$H;H;L/C138 plane in reciprocal space. Elastic scattering reveals the magnetic structure of the ordered phases, while inelastic scattering informs on the elementary spin excitations of these states. Preexisting neutron scattering measurements [7,10] identified the zero-applied-field ordering wave vector as the (2,2,0) Bragg reflection. This result is confirmed in Fig. 2, where a dramatic enhancement of scattering intensity at (2,2,0) is observed upon cooling below the temperature of the heat capacity anomaly. However, we also note that a second, broad component to the scattering is evident. As is clear from Fig. 2(f), when subjected to an applied magnetic field, the magnetic reflection becomes sharper and the background decreases substantially. This is unambiguous evidence for the existence of a broad, diffuse component to the scattering in zero applied magnetic field is clear, indicating short-range magnetic correlations that coexist with long-range order.

Within the $[H, H, L]$ plane, we have measured the magnetic scattering intensity of five distinct Bragg peaks at low temperature ($T = 50$ mK) as a function of applied magnetic field [Fig. 3(c)]. In weak fields, the scattering is dominated by the large (2,2,0) peak associated with the zero magnetic field ground state [Fig. 3(a)]. An anomalous increase is observed in the scattering intensity at the ordering wave vector for $\mu_0H = 0.5$ T. This effect has been ascribed to the creation of a single domain state in previous work [7]; however, we attribute it to the elimination of the short-range correlations that we have observed in zero field (see Fig. 2). As we approach $H_c$ from below, the intensity at (2,2,0) drops off smoothly as long-range order is destroyed. Simultaneously, new intensity develops at the (2,2,2) position, which dominates the scattering in high magnetic field. Strong scattering at (2,2,2) is consistent with a highly polarized $XY$ state, as illustrated in Fig. 3(b).

The boundary between the (2,2,0) and (2,2,2) dominated phases coincides with the quantum critical point deduced from heat capacity in Fig. 1. However, the field-induced reorganization of scattering intensity is not sharp at the critical point. Rather, a smooth evolution is seen for fields within $\sim 1$ T of $\mu_0H_c$. We also observe an increase in
scattering intensity at the (0,0,2) position for $H \sim H_c$, although this magnetic Bragg peak is weak at both low and high fields.

The field evolution of the magnetic scattering is qualitatively understood as a smooth deformation of the ground state from configuration $A$ [illustrated in Fig. 3(a)] to configuration $B$ [illustrated in Fig. 3(b)]. To visualize this, it is useful to subdivide the pyrochlore lattice into spins residing on two sets of orthogonal chains, colored red and blue in Figs. 3(a) and 3(b). To go from $A$ to $B$, it is necessary to rotate all blue spins by $90^\circ$ such that they polarize along $\hat{H}$, while half of the red spins must rotate by $180^\circ$ and half need not move at all. A simple picture emerges in which all spins initially rotate through $90^\circ$, fully polarizing the blue spins while maintaining antiferromagnetic correlations between the red spins. This leads to a polarized coplanar state, where blue spins point along $[1,1,0]$ and red spins point along $\pm[1,−1,0]$. Next, while the blue spins remain pinned along the $[1,1,0]$ direction, the red spins rotate through another $90^\circ$, maximizing their projections along the applied field direction and smoothly increasing the scattering at $(2,2,2)$. This picture gives rise to the calculated Bragg intensities displayed in Fig. 3(d).

The above scenario describes the evolution of only one of the six degenerate low-field states into the unique polarized high-field state. A more realistic picture needs to take into account coexisting domains of all six $A$-type states subject to a global symmetry-lowering $[1,1,0]$ magnetic field. In this context, the quantum critical point at $H_c$ is most likely related to a field-induced merging of ground states, as recently predicted for Gd-based pyrochlores [18]. Nevertheless, we expect the qualitative description of a manifold of smoothly field-deformed states to survive more sophisticated analysis, given the striking similarities between the observed and calculated Bragg intensities.

Complementary to our diffraction results, we report inelastic neutron scattering measurements of the low-energy excitations of $\text{Er}_2\text{Ti}_2\text{O}_7$ across the phase diagram. Excitations have been measured throughout the $[H,H,L]$ plane, and a subset of these results are reported in Fig. 4. In zero applied magnetic field, the onset of magnetic order is accompanied by the appearance of well defined spin wave excitations. Two modes are easily seen near the $(2,2,0)$ position, one being essentially dispersionless at $4\text{ meV}$ while the other goes soft at the ordering wave vector, identifying it as a Goldstone mode. The dispersionless mode was reported previously, along with the absence of the soft mode [7]. It has been argued that the unusual ground state of $\text{Er}_2\text{Ti}_2\text{O}_7$ lacks soft spin excitations, or

![FIG. 3](color online). (a) Schematic diagram of one of six degenerate ground states in zero field. (b) A schematic diagram of the high-field ground state. The spins are fully polarized within $XY$ planes and the state is nondegenerate. Note that spins are subdivided into two sets, residing on perpendicular chains and coloured red and blue. (c) The measured field dependence of the integrated magnetic Bragg intensity of $Q = 0$ peaks at $T = 50\text{ mK}$. The nuclear component to the scattering is eliminated by subtracting data taken at 2 K. (d) Calculated magnetic Bragg scattering is shown for a smooth deformation of the magnetic structure taking it from (a) to (b). A canting angle of $0^\circ$ corresponds to (a) while $180^\circ$ corresponds to (b).

![FIG. 4](color online). The dispersion of spin waves is shown along the $[2,2,L]$ line in reciprocal space, joining the $(220)$ and $(222)$ wave vectors, where Bragg scattering characteristic of the low- and high-field low temperature states is observed. (a) Shows data at $T = 2\text{ K}$ and $H = 0$, while (b)–(h) show data at $T = 50\text{ mK}$ and applied field as indicated. A full spin excitation softening is observed for $\mu_0H \sim 1.5\text{ T}$. 

147205-3
that the lowest energy modes fail to couple to the neutron [7]. Here, we explicitly show that gapless, Goldstone spin excitations exist, since we observe spin waves which go to zero energy at (2,2,0), (1,1,1) and (1,1,3). This unambiguously resolves a long-standing point of confusion: unconventional as it may be, the zero-field ground state does indeed support soft spin excitations.

Under the application of finite magnetic fields, the excitation spectrum displays a rich evolution. At $\mu_0 H = 0.5$ T, the increase in elastic scattering at (2,2,0) is accompanied by the elimination of the soft mode at the same position in reciprocal space. Clearly, the application of such weak fields does not simply create a single domain state, but rather it induces a qualitative change in the ground state. In this regime, spin excitations are still seen to go soft at (1,1,1) and (1,1,3), but not at (2,2,0). Application of stronger fields splits the dispersionless feature into two flat modes, the lower of which decreases towards zero energy transfer. This mode softening is expected at a second order quantum critical point, where the Zeeman energy of dispersionless modes are seen. The existence of two such modes is clear at 2 and 3 T, showing that the high-field ground state does not correspond to a simple disordered paramagnet. Certainly, the difference between the excitation spectra of the quantum paramagnetic phase [Fig. 4(f)], and that of the thermal paramagnet [Fig. 4(a)] is undeniable. In larger applied fields, the ground state is dominated by Zeeman energy. This is evident at 5 T, where two dispersionless modes are seen. The existence of two such modes is indicative of the subdivision of the pyrochlore lattice discussed earlier, where the Zeeman energy of polarized red and blue spins are not equivalent due to local planar anisotropy.

To conclude, the low temperature phase diagram of Er$_2$Ti$_2$O$_7$ supports a rich variety of elementary excitations as the ground state is tuned by external applied field. The most dramatic variation with field occurs around $\mu_0 H_c \sim 1.5$ T, where a seemingly continuous quantum critical point is observed. The degree to which this landscape of low-energy states and quantum critical behavior can be understood will hinge upon a proper energetic description of the system, and we hope this work will guide theoretical efforts in that pursuit.

We thank M. J. P. Gingras, A. G. del Maestro, and K. A. Ross for useful discussions. We acknowledge the technical assistance of E. Fitzgerald, and the use of the DAVE software package for elements of the data reduction and analysis [19].
